0 Introduction

The theory of valuations on convex sets is a classical part of convexity with traditionally strong relations to integral geometry. Approximately during the last 15 years there was a considerable progress in the valuations theory and its applications to integral geometry. The progress is both conceptual and technical: several new structures on valuations have been discovered, new classification results of various special classes of valuations have been obtained, the tools used in the valuations theory and the relations of it to other parts of mathematics have become much more diverse (besides convexity and integral geometry, one can mention representation theory, geometric measure theory, elements of contact geometry and complex and quaternionic analysis). This progress in the valuations theory has led to new developments in integral geometry, particularly in Hermitian spaces. Some of the new structures turned out to encode in an elegant and useful way an important integral geometric information: for example the product on valuations encodes somehow the principal kinematic formulas in various spaces.

Quite recently, generalizations of the classical theory of valuations on convex sets to the context of manifolds were initiated; this development extends the applicability of the valuations theory beyond affine spaces, and also covers a broader scope of integral geometric problems. In particular, the theory of valuations on manifolds provides a common point of view on three classical and previously unrelated directions of integral geometry: Crofton style integral geometry dealing with integral geometric and differential geometric invariants of sets and their intersections with and projections to lower dimensional subspaces; Gelfand style integral geometry dealing with the Radon transform on smooth functions on various spaces; and less classical but still well known the Radon transform with respect to the Euler characteristic on constructible functions.

The relations between the valuations theory and the Crofton style integral geometry have been known since the works of Blaschke and especially Hadwiger, but the new developments have enriched the both subjects, and in fact more progress is expected. The relations of the valuations theory to the two other types of integral geometry are new.

Besides new notions, theorems, and applications, these recent developments contain a fair amount of new intuition on the subject. However when one tries to make this intuition formally precise, the clarity of basic ideas is often lost among numerous technical details; moreover in a few cases this formalization has not been done yet. Here in several places I take the opportunity to use the not very formal format of lecture notes to explain the new intuition in a heuristic way, leaving the technicalities aside. Nevertheless I clearly separate formal rigorous statements from such heuristic discussions.

The goal of my and Joe Fu's lectures is to provide an introduction to these modern developments. These two sets of lectures complement each other. My lectures concentrate mostly on the valuations theory itself and provide a general background for Fu's lectures.

In my lectures the discussion of the relations between the valuations theory and integral geometry is usually relatively brief, and its goal is to give simple illustrations of general notions. The important exceptions are Sections 2.10 and 2.11 where new integral geometric results are discussed, namely a Radon type transform on valuations. Much more thorough discussion of applications to Crofton style integral geometry, especially in Hermitian spaces, will be given in Fu's lectures.

My lectures consist of two main parts. The first part discusses the theory of valuations on convex sets, and the second part discusses its recent generalizations to manifolds. The theory of valuations on convex sets is a very classical and much studied area. In these lectures I mention only several facts from these classical developments which are necessary for our purposes; I refer to the surveys [55], [54] for further details and history.

These lectures contain almost no proofs. I tried to give the necessary definitions and list the main properties and sometimes present constructions of the principal objects and some intuition behind. Among important new operations on valuations are product, convolution, Fourier type transform, pull-back, push-forward, and the Radon type transform on valuations; all of them are relevant to integral geometry and are discussed in these notes.

Several interesting recent developments in the valuations theory are not discussed here. The main omissions are a series of investigations by M. Ludwig with collaborators of valuations with weaker assumptions on continuity and various symmetries (see e.g. [51], [48], [50]) and convex bodies valued valuations (see e.g. [47], [49], [60]). Particularly let me mention the surprising Ludwig-Reitzner characterization [51] of the affine surface area as the only (up to the Euler characteristic, volume, and a non-negative multiplicative factor) example of upper semi-continuous convex valuation invariant under all affine volume preserving transformations.

Acknowledgements. These are notes of my lectures to be given at Centre de Recerca Matemàtica during the Advanced Course on Integral Geometry and Valuation Theory; I thank this institution and the organizers of the course E. Gallego, X. Gual, G. Solanes, and E. Teufel, for the invitation to give these lectures. I thank A. Bernig for his remarks on the first version of the notes, and F. Schuster for a very careful reading of them and numerous remarks.

1 Translation invariant valuations on convex sets.

1.1 Definitions.

Let V be a finite dimensional vector space of dimension n . Throughout these notes we will denote by $\mathcal{K}(V)$ the family of all convex compact non-empty subsets of V .

Definition 1.1.1. A complex valued functional

$$\phi: \mathcal{K}(V) \rightarrow \mathbb{C}$$

is called a valuation if

$$\phi(A \cup B) = \phi(A) + \phi(B) - \phi(A \cap B)$$

whenever $A, B, A \cup B \in \mathcal{K}(V)$.

Remark 1.1.2. In Section 2 we will introduce a different but closely related notion of valuation on a smooth manifold. To avoid abuse of terminology, we will sometimes call valuations on convex sets in from Definition 1.1.1 by *convex valuations*, though this is not a traditional terminology. But when it does not lead to abuse of terminology, we will call them just valuations. In fact all valuations from Section 1 will be convex, while from Section 2 will not unless otherwise stated.

Example 1.1.3. (1) Any $\mathbb{C}$ -valued measure on V is a convex valuation. In particular the Lebesgue measure is.

(2) The Euler characteristic χ defined by $\chi(K) = 1$ for any $K \in \mathcal{K}(V)$, is a convex valuation.

(3) Let ϕ be a convex valuation. Let $C \in \mathcal{K}(V)$ be fixed. Define

$$\psi(K) := \phi(K + C).$$

Then ψ is a convex valuation. (Here $K + C := \{k + c | k \in K, c \in C\}$ is the Minkowski sum.) Indeed $(A \cup B) + C = (A + C) \cup (B + C)$, and if $A, B, A \cup B \in \mathcal{K}(V)$ then

$$(A \cap B) + C = (A + C) \cap (B + C).$$

Let us define a very important class of continuous convex valuations. Fix a Euclidean metric on V . The Hausdorff distance on $\mathcal{K}(V)$ is defined by

$$\text{dist}_H(A, B) := \inf\{\varepsilon > 0 | A \subset (B)_\varepsilon, B \subset (A)_\varepsilon\}$$

where $(A)_\varepsilon$ denotes the ε -neighborhood of A in the Euclidean metric. It is well known (see e.g. [58]) that $\mathcal{K}(V)$ equipped with dist_H is a metric locally compact space in which any closed bounded set is compact.

Definition 1.1.4. A convex valuation $\phi: \mathcal{K}(V) \rightarrow \mathbb{C}$ is called continuous if ϕ is continuous in the Hausdorff metric.

Readily this notion of continuity of a valuation is independent of the choice of a Euclidean metric on V .

Definition 1.1.5. A convex valuation $\phi: \mathcal{K}(V) \rightarrow \mathbb{C}$ is called translation invariant if

$$\phi(K + x) = \phi(K) \text{ for any } K \in \mathcal{K}(V), x \in V.$$

The linear space of translation invariant continuous convex valuations will be denoted by $\text{Val}(V)$. Equipped with the topology of uniform convergence on compact subsets of $\mathcal{K}(V)$, $\text{Val}(V)$ is a Fréchet space. In fact it follows from McMullen's decomposition (Corollary 1.2.2 below) that $\text{Val}(V)$ with this topology is a Banach space with a norm is given by

$$\|\phi\| := \sup_{K \subset D} |\phi(K)|,$$

where $D \subset V$ is the unit Euclidean ball for some auxiliary Euclidean metric.

1.2 McMullen's theorem and mixed volumes.

The following result due to McMullen [52] is very important.

Theorem 1.2.1. *Let $\phi: \mathcal{K}(V) \rightarrow \mathbb{C}$ be a translation invariant continuous convex valuation. Then for any convex compact sets $A_1, \dots, A_s \in \mathcal{K}(V)$ the function*

$$f(\lambda_1, \dots, \lambda_s) := \phi(\lambda_1 A_1 + \dots + \lambda_s A_s)$$

with $\lambda_1, \dots, \lambda_s \geq 0$ is a polynomial of degree at most $n = \dim V$.

The special case $s = 1$ is already non-trivial and important. It means that for $\lambda \geq 0$

$$\phi(\lambda K) = \phi_0(K) + \lambda \phi_1(K) + \dots + \lambda^n \phi_n(K).$$

It is easy to see that the coefficients $\phi_0, \phi_1, \dots, \phi_n$ are also continuous translation invariant convex valuations. Moreover ϕ_i is homogeneous of degree i (or i -homogeneous for brevity). By definition, a valuation ψ is called i -homogeneous if for any $K \in \mathcal{K}(V)$, $\lambda \geq 0$ one has

$$\phi(\lambda K) = \lambda^i \phi(K).$$

Let us denote by $Val_i(V)$ the subspace in $Val(V)$ of i -homogeneous valuations. We immediately get the following corollary:

Corollary 1.2.2 (McMullen's decomposition).

$$Val(V) = \oplus_{i=0}^n Val_i(V).$$

Remark 1.2.3. Clearly $Val_0(V)$ is one dimensional and is spanned by the Euler characteristic. Actually $Val_n(V)$ is also one dimensional and is spanned by a Lebesgue measure; this fact is not obvious and was proved by Hadwiger [39].

Let us now recall the definition of (Minkowski's) mixed volumes which provide interesting examples of translation invariant continuous convex valuations. Fix a Lebesgue measure vol on V . For any n tuple of convex compact sets $A_1, \dots, A_n$ consider the function

$$f(\lambda_1, \dots, \lambda_n) = vol(\lambda_1 A_1 + \dots + \lambda_n A_n).$$

This is a homogeneous polynomial in $\lambda_i \geq 0$ of degree n . Of course, this fact follows from McMullen's theorem 1.2.1 and n -homogeneity of the volume, though originally it was discovered much earlier by Minkowski, and in this particular case there is a simpler proof (see e.g. [58]).

Definition 1.2.4. The coefficient of the monomial $\lambda_1 \dots \lambda_n$ in the polynomial $f(\lambda_1, \dots, \lambda_n)$ divided by $n!$ is called the mixed volume of $A_1, \dots, A_n$ and is denoted by $V(A_1, \dots, A_n)$.

The normalization of the coefficient is chosen in such a way that $V(A, \dots, A) = vol(A)$. Mixed volumes have a number of interesting properties, in particular they satisfy the Aleksandrov-Fenchel inequality [58]. The property relevant for us however is the valuation property. Fix $1 \leq s \leq n - 1$ and an s -tuple of convex compact sets $A_1, \dots, A_s$. Define

$$\phi(K) = V(K[n - s], A_1, \dots, A_s) \tag{1.1}$$

where $K[n - s]$ means that K is taken $n - s$ times. Then ϕ is a translation invariant continuous valuation. This easily follows from Example 1.1.3(3).

1.3 Hadwiger's theorem.

One of the most famous and classical results of the valuations theory is Hadwiger's classification of isometry invariant continuous convex valuations on the Euclidean space $\mathbb{R}^n$. To formulate it, let us denote by V_i the i -th intrinsic volume, which by definition is

$$V_i(K) = c_{n,i} V(K[i], D[n-i])$$

where $c_{n,i}$ is an explicitly written constant which is just a standard normalization (see [58]). In particular $V_0 = \chi$ is the Euler characteristic, $V_n = \text{vol}$ is the Lebesgue measure normalized so that the volume of the unit cube is equal to 1. Clearly $V_i \in \text{Val}_i$ is an $O(n)$ -invariant valuation.

Theorem 1.3.1 (Hadwiger's classification [39]). *Any $SO(n)$ -invariant translation invariant continuous convex valuation is a linear combination of $V_0, V_1, \dots, V_n$. (In particular it is $O(n)$ -invariant.)*

In 1995 Klain [43] has obtained a simplified proof of this deep result as an easy consequence of his classification of simple even valuations discussed below in Section 1.5. Hadwiger's theorem turned out to be very useful in integral geometry of the Euclidean space. This will be discussed in more detail in J. Fu's lectures. We also refer to the book [45].

1.4 Irreducibility theorem.

One of the basic questions of the valuations theory is to describe valuations with given properties. Hadwiger's theorem is one example of such a result of great importance. In recent years there were obtained a number of classification results of various classes of valuations. The case of continuous translation invariant valuations will be discussed in detail in these lectures below and in lectures by Fu.

The question is whether it is possible to give a reasonable description of all translation invariant continuous convex valuations. In 1980 P. McMullen [53] has formulated a more precise conjecture which says that linear combinations of mixed volumes (as in (1.1)) are dense in Val . This conjecture was proved in positive by the author [2] in a stronger form which later on turned out to be important in further developments and applications.

To describe the result let us make a few more remarks. We say that a valuation ϕ is even (resp. odd) if $\phi(-K) = \phi(K)$ (resp. $\phi(-K) = -\phi(K)$) for any $K \in \mathcal{K}(V)$. The subspace of even (resp. odd) i -homogeneous valuations will be denoted by Val_i^+ (resp. Val_i^-). Clearly

$$\text{Val}_i = \text{Val}_i^+ \oplus \text{Val}_i^-. \quad (1.2)$$

Next observe that the group $GL(V)$ of all invertible linear transformations acts linearly on Val :

$$(g\phi)(K) = \phi(g^{-1}K).$$

Theorem 1.4.1 (Irreducibility theorem [2]). *For each i , the spaces $\text{Val}_i^+, \text{Val}_i^-$ are irreducible representations of $GL(V)$, i.e. they do not have proper invariant closed subspaces.*

Remark 1.4.2. By Remark 1.2.3 $Val_0^+ = Val_0$, $Val_n^+ = Val_n$ are one dimensional. But for $1 \leq i \leq n-1$ the spaces $Val_i^\pm$ are infinite dimensional. Val_{n-1} was explicitly described by McMullen [53]; we state his result in Section 1.5 below.

Theorem 1.4.1 immediately implies McMullen's conjecture. Indeed it is easy to see that the closure of the linear span of mixed volumes is a $GL(V)$ -invariant subspace, and its intersection with any $Val_i^\pm$ is non-zero. Hence by the irreducibility theorem any such intersection should be equal to the whole space $Val_i^\pm$.

The irreducibility theorem will be used in these lectures several times. The proof of this result uses a number of deep results from the valuations theory in combination with representation theoretical techniques. A particularly important such result of high independent interest is the Klain-Schneider classification of *simple* translation invariant continuous convex valuations; it is discussed in the next section.

1.5 Klain-Schneider characterization of simple valuations.

Definition 1.5.1. A convex valuation $\phi \in Val$ is called simple if $\phi(K) = 0$ for any $K \in \mathcal{K}(V)$ with $\dim K < n := \dim V$.

Theorem 1.5.2. (i) [Klain [43]] Any simple even valuation from Val is proportional to the Lebesgue measure.

(ii) [Schneider [59]] Any simple odd valuation from Val is $(n-1)$ -homogeneous.

Clearly any simple valuation is the sum of a simple even and a simple odd valuations. Hence in order to complete the description of simple valuations it remains to classify simple $(n-1)$ -homogeneous valuations. Fortunately McMullen [53] has previously described Val_{n-1} very explicitly. His result was used in Schneider's proof, and it is worthwhile to state it explicitly as it has independent interest.

First let us recall the definition of the area measure $S_{n-1}(K, \cdot)$ of a convex compact set K . Though it is not strictly necessary, it is convenient and common to fix a Euclidean metric on V . After this choice, $S_{n-1}(K, \cdot)$ is a measure on the unit sphere S^{n-1} defined as follows. First let us assume that K is a polytope. For any $(n-1)$ -face F let us denote by n_F the unit outer normal at F . Then by definition

$$S_{n-1}(K, \cdot) = \sum_F \text{vol}_{n-1}(F) \delta_{n_F},$$

where the sum runs over all $(n-1)$ -faces of K , and δ_{n_F} denotes the delta-measure supported at n_F . Then the claim is that the area measure extends uniquely by weak continuity to the class of all convex compact sets: if $K_N \rightarrow K$ in the Hausdorff metric then $S_{n-1}(K_N, \cdot) \rightarrow S_{n-1}(K, \cdot)$ weakly in the sense of measures (see [58], §4.2).

Theorem 1.5.3 (McMullen, [53]). Let $\phi \in Val_{n-1}$, $n = \dim V$. Then there exists a continuous function $f: S^{n-1} \rightarrow \mathbb{C}$ such that

$$\phi(K) = \int_{S^{n-1}} f(x) dS_{n-1}(K, x).$$

Conversely, any expression of this form with a continuous f is a valuation from Val_{n-1} .

Moreover two continuous functions f and g define the same valuation if and only if the difference $f - g$ is a restriction of a linear functional on V to the unit sphere.

Now we can summarize the classification of simple valuations.

Theorem 1.5.4 (Klain-Schneider). *Simple translation invariant continuous valuations are precisely of the form*

$$K \mapsto c \cdot \text{vol}_n(K) + \int_{S^{n-1}} f(x) dS_{n-1}(K, x),$$

where $f: S^{n-1} \rightarrow \mathbb{C}$ is an odd continuous function, and c is a constant. Moreover the constant c is defined uniquely, while f is defined up to a linear functional.

1.6 Smooth translation invariant valuations.

We are going to describe an important subspace of Val of *smooth* valuations. They form a dense subspace in Val and carry a number of extra structures (e.g. product, convolution, Fourier transform) which do not extend by continuity to the whole space Val of continuous valuations. Moreover main examples relevant to integral geometry are in fact smooth valuations.

Definition 1.6.1. A valuation $\phi \in Val(V)$ is called smooth if the Banach space valued map $GL(V) \rightarrow Val(V)$ given by $g \mapsto g(\phi)$ is infinitely differentiable.

From a very general and elementary representation theoretical reasoning, the subset of smooth valuations, denoted by $Val^{sm}(V)$, is a linear dense subspace of $Val(V)$ invariant under the natural action of $GL(V)$. Also $Val^{sm}(V)$ carries a linear topology which is stronger than that induced from $Val(V)$, and with respect to which it is a Fréchet space. This is called often the Garding topology, and tacitly we will always assume that $Val^{sm}(V)$ is equipped with it. Of course, Val^{sm} also satisfies McMullen's decomposition and the irreducibility theorem.

For future applications to integral geometry, the following result will be important.

Proposition 1.6.2 ([4]). *Let G be a compact subgroup of the orthogonal group of a Euclidean space V . Assume that G acts transitively on the unit sphere of V . Then any G -invariant valuation from $Val(V)$ is smooth.*

1.7 Product on smooth translation invariant valuations and Poincaré duality.

In this section we discuss the product on translation invariant smooth valuations introduced in [4]. This structure turned out to be intimately related to integral geometric formulas discussed in detail in J. Fu's lectures.

First we will introduce exterior product on valuations.

Theorem 1.7.1 ([4]). *Let V and W be finite dimensional real vector spaces. There exists a continuous bilinear map, called exterior product,*

$$Val^{sm}(V) \times Val^{sm}(W) \rightarrow Val(V \times W)$$

which is uniquely characterized by the following property: Fix $A \in \mathcal{K}(V)$, $B \in \mathcal{K}(W)$. Let vol_V, vol_W be Lebesgue measures on V, W respectively. Let $\phi(K) = vol_V(K + A)$, $\psi(K) = vol_W(K + B)$. Then their exterior product, denoted by $\phi \boxtimes \psi$, is

$$(\phi \boxtimes \psi)(K) = vol_{V \times W}(K + (A \times B)) \text{ for any } K \in \mathcal{K}(V \times W),$$

where $vol_{V \times W}$ is the product measure of vol_V and vol_W .

Notice that the uniqueness in this theorem follows immediately from the (proved) McMullen's conjecture since linear combinations of valuations of the form $vol(\bullet + A)$ are dense in valuations.

Let us emphasize that the exterior product is defined on smooth valuations, but it takes values not in smooth but just continuous valuations. Usually the exterior product is not smooth. Let us give some examples.

Example 1.7.2. 1) The exterior product of Lebesgue measures in the sense of valuations coincides obviously with their measure theoretical product.

2) The exterior product of Euler characteristics is the Euler characteristic on $V \times W$.

3) Let vol_V be a Lebesgue measure on V , and χ_W be the Euler characteristic on W . Then the exterior product $vol_V \boxtimes \chi_W$ is the volume of the projection to V :

$$(vol_V \boxtimes \chi_W)(K) = vol_V(pr_V(K)) \text{ for any } K \in \mathcal{K}(V \times W),$$

where $pr_V: V \times W \rightarrow V$ is the natural projection. Observe that this valuation is not smooth (in contrast to the first two examples.)

The first non-trivial point in Theorem 1.7.1 is that the exterior product is well defined, the second one is continuity. We do not give here any proof. However let us give an incomplete, but instructive, explanation why the exterior product is well defined. There are of course many different ways to write a valuation as a linear combinations of $vol(\bullet + A)$. Let us see that the exterior product of finite linear combinations of such expressions is independent of the particular choice of a linear combination. Since the situation is symmetric with respect to both valuations, we may assume that $\phi(\bullet) = \sum_i c_i \cdot vol_V(\bullet + A_i)$ and $\psi(\bullet) = vol_W(\bullet + B)$. Then using the Fubini theorem and the equality $A_i \times B = (A_i \times 0) + (0 \times B)$ we get

$$\begin{aligned} (\phi \boxtimes \psi)(K) &= \sum_i c_i \cdot vol_{V \times W}(K + (A_i \times B)) = \\ &= \sum_i c_i \cdot \int_{w \in W} vol_V[\{(K + (0 \times B)) \cap (V \times \{w\})\} + A_i] dvol_W(w) = \\ &= \int_{w \in W} \phi[(K + (0 \times B)) \cap (V \times \{w\})] dvol_W(w). \end{aligned}$$

Clearly the last expression is independent of the form of presentation of ϕ .

Now let us define the product on Val^{sm} . Let us denote by

$$\Delta: V \rightarrow V \times V$$

the diagonal imbedding. The product of $\phi, \psi \in Val^{sm}(V)$ is defined by

$$(\phi \cdot \psi) := (\phi \boxtimes \psi)(\Delta(K)).$$

It turns out that the product of smooth valuations is again smooth.

Theorem 1.7.3 ([4]). *The product of smooth valuations $Val^{sm}(V) \times Val^{sm}(V) \rightarrow Val^{sm}(V)$ is continuous (in the Garding topology), associative, commutative, and distributive. Then $Val^{sm}(V)$ becomes an algebra over $\mathbb{C}$ with unit which is the Euler characteristic. Moreover the product respects the degree of homogeneity:*

$$Val_i^{sm} \cdot Val_j^{sm} \subset Val_{i+j}^{sm}.$$

Example 1.7.4. The product of intrinsic volumes $V_i \cdot V_j$ with $i+j \leq n$ is a non-zero multiple of V_{i+j} : by the Hadwiger theorem it is clear that the product should be proportional to V_{i+j} , the constant of proportionality can be computed explicitly.

An interesting property of the above product is a version of the Poincaré duality.

Theorem 1.7.5 ([4]). *For any $i = 0, 1, \dots, n = \dim V$ the bilinear map*

$$Val_i^{sm}(V) \times Val_{n-i}^{sm}(V) \rightarrow Val_n^{sm}(V)$$

is a perfect pairing, namely for any non-zero valuation $\phi \in Val_i^{sm}(V)$ there exists $\psi \in Val_{n-i}^{sm}(V)$ such that $\phi \cdot \psi \neq 0$.

This result follows easily from the Irreducibility Theorem 1.4.1. Indeed it suffices to prove the statement for valuations of fixed parity $\varepsilon = \pm 1$. Then the kernel of the above pairing in $Val_i^{\varepsilon, sm}(V)$ is a $GL(V)$ -invariant closed subspace. Hence it must be either zero or everything. But it cannot be everything since then for any valuation $\psi \in Val_{n-i}^{sm}(V)$ one would have $\psi \cdot Val_i^{\varepsilon, sm}(V) = 0$. But this is not the case as can be easily proved by constructing an explicit example. (Say in the even case, the product of the intrinsic volumes $V_i \cdot V_{n-i}$ is a non-zero multiple of Lebesgue measure.)

Thus $Val^{sm}(V)$ is a graded algebra satisfying the Poincaré duality. In Section 1.10 we will see also that it satisfies two versions of the hard Lefschetz theorem.

1.8 Pull-back and push-forward of translation invariant valuations.

In this section we describe the operations of pull-back and push-forward on translation invariant valuations under linear maps.

Let $f: V \rightarrow W$ be a linear map. We define [14] the continuous linear map, called pull-back,

$$f^*: Val(W) \rightarrow Val(V)$$

defined as usual by $(f^*\phi)(K) = \phi(f(K))$. It is easy to see that $f^*\phi$ is indeed a continuous translation invariant convex valuation. The following result is evident.

Proposition 1.8.1. (i) f^* preserves the degree of homogeneity and parity.

(ii) $(f \circ g)^* = g^* \circ f^*$.

Notice that the product on valuations can be expressed via the exterior product and the pull-back by

$$\phi \cdot \psi = \Delta^*(\phi \boxtimes \psi),$$

where Δ is the diagonal imbedding.

A somewhat less obvious operation is push-forward f_* introduced in [14]. In some non-precise sense f_* is dual to f^* . In these notes it will be used only to give an alternative description of the convolution on valuations in Section 1.9 and to clarify some properties of the Fourier type transform on valuations in Section 1.11; the reader not interested in these subjects may skip the rest of this section.

Canonically the push-forward map acts not between spaces of valuations, but between their tensor product (twist) by an appropriate one dimensional space of Lebesgue measures. To be more precise let us denote by $D(V^*)$ the one dimensional space of ($\mathbb{C}$ -valued) Lebesgue measures on V^* . Then f_* is a linear continuous map

$$f_*: Val(V) \otimes D(V^*) \rightarrow Val(W) \otimes D(W^*).$$

In order to define this map, we will split its construction to the cases of f being injective, surjective, and a general linear map.

Case 1. Let f be injective. Thus we may assume that $V \subset W$. In order to simplify the notation we choose a splitting $W = V \oplus L$ and we fix Lebesgue measures on V and L . Then on W we have the product measure. These choices induce isomorphisms $Dens(V^*) \simeq \mathbb{C}$, $Dens(W^*) \simeq \mathbb{C}$. We leave for a reader to check that the construction of f_* is independent of these choices.

Let $\phi \in Val(V)$. Define

$$(f_*\phi)(K) = \int_{l \in L} \phi(K \cap (l + V)) dl.$$

It is easy to see that $f_*: Val(V) \rightarrow Val(W)$ is a continuous linear map.

Case 2. Let f be surjective. Again it will be convenient to assume that f is just a projection to a subspace, and fix a splitting $V = W \oplus M$. Again fix Lebesgue measures on W, M , and hence on V . Let us also fix a set $S \in \mathcal{K}(M)$ of unit measure. Set $m := \dim M$. Then define

$$(f_*\phi)(K) = \frac{1}{m!} \frac{d^m}{d\varepsilon^m} \phi(K + \varepsilon \cdot S) \Big|_{\varepsilon=0}.$$

Recall that by McMullen's theorem $\phi(K + \varepsilon \cdot S)$ is a polynomial in $\varepsilon \geq 0$. Moreover its degree is at most m : Indeed when K is fixed this expression is a translation invariant continuous valuation with respect to $S \in \mathcal{K}(M)$. The coefficient of ε^m is an m -homogeneous valuation with respect to $S \subset M$, and hence by Hadwiger's theorem (see Remark 1.2.3) it must be proportional to the Lebesgue measure on M with a constant depending on K . By our

definition, this coefficient is exactly $(f_*\phi)(K)$, in particular it does not depend on S . In fact it does not depend also on choice of Lebesgue measures and the splitting.

Case 3. Let f be a general linear map. Let us choose a factorization $f = g \circ h$ where $h: V \rightarrow Z$ is surjective, and $g: Z \rightarrow W$ is injective. Then define $f_* := g_* \circ h_*$. One can show that f_* is independent of the choice of such a factorization.

Proposition 1.8.2 ([14], Section 3.2). *(i) $f_*: Val(V) \otimes D(V^*) \rightarrow Val(W) \otimes D(W^*)$ is a continuous linear operator.*

(ii) $(f \circ g)_* = f_* \circ g_*$.

(iii) $f_*(Val_i(V) \otimes D(V^*)) \subset Val_{i-\dim V+\dim W}(W) \otimes D(W^*)$.

1.9 Convolution.

In this section we describe another interesting operation on valuations: a convolution introduced by Bernig and Fu [24]. This is a continuous product on $Val^{sm} \otimes D(V^*)$. Let us fix for simplicity of the notation a Lebesgue measure vol on V ; it induces a Lebesgue measure on V^* . With these identifications, convolution is going to be defined on $Val^{sm}(V)$ (without the twist by $D(V^*)$).

Theorem 1.9.1 ([24]). *There exists a unique continuous bi-linear map, called convolution,*

$$*: Val^{sm}(V) \times Val^{sm}(V) \rightarrow Val^{sm}(V)$$

such that

$$vol(\bullet + A) * vol(\bullet + B) = vol(\bullet + A + B).$$

This product makes $Val^{sm}(V)$ a commutative associative algebra with the unit element vol . Moreover $Val_i^{sm} * Val_j^{sm} \subset Val_{i+j-n}^{sm}$.

The above result characterizes the convolution uniquely, and allows to compute it in some examples. We can give however one more description of it using the previously introduced operations. Let $a: V \times V \rightarrow V$ be the addition map, namely $a(x, y) = x + y$. Then by [14], Proposition 3.3.2, one has

$$\phi * \psi = a_*(\phi \boxtimes \psi).$$

The product and convolution will be transformed one to the other in Section 1.11 by another useful operation, the Fourier type transform.

1.10 Hard Lefschetz type theorems.

The product and the convolution on valuations satisfy another non-trivial property analogous to the hard Lefschetz theorem from algebraic geometry [36]. Let us fix on V a Euclidean metric. Consider the operator

$$L: Val_*^{sm} \rightarrow Val_{*+1}^{sm}$$

given by $L\phi := \phi \cdot V_1$ where V_1 is the first intrinsic volume as in Section 1.3. Consider also another operator

$$\Lambda: Val_*^{sm} \rightarrow Val_{*-1}^{sm}$$

defined by $(\Lambda\phi)(K) = \frac{d}{d\varepsilon}\phi(K + \varepsilon \cdot D)|_{\varepsilon=0}$ where D is the unit ball (here we use again McMullen's theorem that $\phi(K + \varepsilon \cdot D)$ is a polynomial). Notice that up to a normalizing constant, the operator Λ is equal to the convolution with V_{n-1} , as was observed by Bernig and Fu [24].

Theorem 1.10.1. (i) Let $0 \leq i < \frac{n}{2}$. Then $L^{n-2i}: Val_i^{sm} \rightarrow Val_{n-i}^{sm}$ is an isomorphism.
(ii) Let $\frac{n}{2} < i \leq n$. Then $\Lambda^{2i-n}: Val_i^{sm} \rightarrow Val_{n-i}^{sm}$ is an isomorphism.

Several authors have contributed to the proof of this theorem. First the author proved (i) and (ii) in the even case [6], [3] using the previous joint work with Bernstein [17] and integral geometry on Grassmannians (Radon and cosine transforms). Then Bernig and Bröcker [23] proved part (ii) in the odd case using a very different method: the Laplacian acting on differential forms on the sphere bundle and some results from complex geometry (Kähler identities). Next Bernig and Fu have shown [24] that in the even case, both versions of the hard Lefschetz theorem are in fact equivalent via the Fourier transform (which was at that time defined only for even valuations). Finally the author extended in [14] the Fourier transform to odd valuations and derived the version (i) of the hard Lefschetz theorem in the odd case from version (ii).

1.11 A Fourier type transform on translation invariant convex valuations.

A Fourier type transform on translation invariant smooth valuations is another useful operation. First it was introduced in [3] (under a different name of duality) for even valuations and was applied there to Hermitian integral geometry in order to construct a new basis in the space of $U(n)$ -invariant valuations on $\mathbb{C}^n$. In the odd case it was constructed in [14]. Some recent applications and non-trivial computations of the Fourier transform in Hermitian integral geometry are due to Bernig and Fu [25].

In this section we will describe the general properties of the Fourier transform and its relation to the product and convolution described above. We will present a construction of the Fourier transform in the even case only. The construction in the odd case is more technical, and will not be presented here. Notice that the even case will suffice for a reader interested mostly in applications to integral geometry of affine spaces, since by a result of Bernig [20] any G -invariant valuation from Val must be even provided G is a compact subgroup of the orthogonal group acting transitively on the unit sphere.

The main general properties of the Fourier transform are summarized in the following theorem.

Theorem 1.11.1 ([14]). *There exists an isomorphism of linear topological spaces*

$$\mathbb{F}: Val^{sm}(V) \rightarrow Val^{sm}(V^*) \otimes D(V)$$

which satisfies the following properties:

- 1) $\mathbb{F}$ commutes with the natural action of the group $GL(V)$ on both spaces;
- 2) $\mathbb{F}$ is an isomorphism of algebras when the source is equipped with the product and the target with the convolution.
- 3) The Fourier transform satisfies a Plancherel type inversion formula explained below.

In order to describe the Plancherel type formula and present a more explicit description of the Fourier transform it will be convenient (but not necessary) to fix a Euclidean metric on V . This will induce identifications $V^* \simeq V$ and $D(V^*) \simeq \mathbb{C}$. With these identifications $\mathbb{F}: Val^{sm}(V) \rightarrow Val^{sm}(V)$; actually it changes the degree of homogeneity:

$$\mathbb{F}: Val_i^{sm} \xrightarrow{\sim} Val_{n-i}^{sm}.$$

The Plancherel type formula says, under these identifications, that $(\mathbb{F}^2\phi)(K) = \phi(-K)$.

Here are a few simple examples: $\mathbb{F}(vol) = \chi$; $\mathbb{F}(\chi) = vol$; $\mathbb{F}(V_i) = c_{n,i}V_{n-i}$ where $c_{n,i} > 0$ is a normalizing constant which can be computed explicitly. (Notice that the last fact, except for the positivity of $c_{n,i}$, is an immediate consequence of the fact that $\mathbb{F}$ commutes with the action of $O(n)$ and Hadwiger's theorem.)

The Fourier transform on a 2-dimensional space has an explicit description which we are going to describe now. We will work for simplicity in $\mathbb{R}^2$ with the standard Euclidean metric and standard orientation. With the identifications induced by the metric as above $\mathbb{F}: Val^{sm}(\mathbb{R}^2) \rightarrow Val^{sm}(\mathbb{R}^2)$. It remains to describe $\mathbb{F}$ on 1-homogeneous valuations. Every such smooth valuation ϕ can be written uniquely in the form

$$\phi(K) = \int_{S^1} h(\omega) dS_1(K, \omega)$$

where $h: S^1 \rightarrow \mathbb{C}$ is a smooth function which is orthogonal on S^1 to the two dimensional space of linear functionals. Let us decompose h to the even and odd parts:

$$h = h_+ + h_-.$$

Let us decompose further the odd part h_- to "holomorphic" and "anti-holomorphic" parts

$$h_- = h_-^{hol} + h_-^{anti}$$

as follows. Let us decompose h_- to the usual Fourier series on the circle S^1 :

$$h_-(\omega) = \sum_k \hat{h}_-(k) e^{ik\omega}.$$

Then by definition

$$\begin{aligned} h_-^{hol}(\omega) &:= \sum_{k>0} \hat{h}_-(k) e^{ik\omega}, \\ h_-^{anti}(\omega) &:= \sum_{k<0} \hat{h}_-(k) e^{ik\omega}. \end{aligned}$$

Then the Fourier transform of the valuation ϕ is equal to

$$(\mathbb{F}\phi)(K) = \int_{S^1} (h_+(J\omega) + h_-^{hol}(J\omega)) dS_1(K, \omega) - \int_{S^1} h_-^{anti}(J\omega) dS_1(K, \omega)$$

where J is the rotation of $\mathbb{R}^2$ by $\frac{\pi}{2}$ counterclockwise. (Notice the minus sign before the second integral.) Observe that $\mathbb{F}$ preserves the class of real valued even valuations, but for odd real valued valuations this is not true. This phenomenon also holds in higher dimensions.

Let us consider even valuations in arbitrary dimension. We again fix a Euclidean metric on V . A useful tool in studying even valuations is an imbedding of $Val_i^+(V)$ to the space of continuous functions on the Grassmannian $Gr_i(V)$ of i -dimensional subspaces of V . It was constructed by Klain [44] as an easy consequence of his classification of simple even valuation (Theorem 1.5.2(a)). Define the map

$$Kl_i: Val_i^+(V) \rightarrow C(Gr_i(V))$$

as follows. Let $\phi \in Val_i^+(V)$. For any $E \in Gr_i(V)$ the restriction of ϕ to E is a valuation of maximal degree of homogeneity. Hence by a result of Hadwiger it must be proportional to Lebesgue measure vol_E induced by the Euclidean metric. Thus by definition

$$\phi|_E = (Kl_i(\phi))(E) \cdot vol_E.$$

Clearly $Kl_i(\phi)$ is a continuous function and Kl_i is a continuous linear $O(n)$ -equivariant linear map. The non-trivial fact is that Kl_i is *injective*. For we observe that if $\phi \in Ker(Kl_i)$ then the restriction of ϕ to any $i+1$ -dimensional subspace is a simple, even, i -homogeneous valuation. Hence it vanishes by Klain's theorem. Proceeding by induction, one sees that $\phi = 0$.

Next it is not hard to see that smooth valuations are mapped under Kl_i to infinitely smooth functions on $Gr_i(V)$. Let us define the Fourier transform $\mathbb{F}: Val_i^{+,sm} \rightarrow Val_{n-i}^{+,sm}$ by the following property: for any subspace $E \in Gr_{n-i}(V)$,

$$(Kl_{n-i}(\mathbb{F}\phi))(E) = (Kl_i(\phi))(E^\perp),$$

where as usual $E^\perp$ denotes the orthogonal complement. This condition characterizes $\mathbb{F}$ uniquely in the even case. The non-trivial point is the existence of $\mathbb{F}$ with this property. The problem is that the Klain imbedding $Kl_i: Val_i^{+,sm}(V) \hookrightarrow C^\infty(Gr_i(V))$ is not onto (for $i \neq 1, n-1$). The main point is to show that this image is invariant under taking the orthogonal complement. It was shown by Bernstein and the author [17] that the image of Kl_i coincides with the image of the so called cosine transform on Grassmannians; this step used also the irreducibility theorem. From the definition of the cosine transform (which we do not reproduce here) it is easy to see that its image is invariant under taking the orthogonal complement.

Let us add a couple of words on the odd case. There is a version of Klain's imbedding for odd valuations though it is more complicated: $Val_i^{-,sm}(V)$ is realized as a quotient of a subspace of functions on a manifold of partial flags (here instead of Klain's characterization of simple even valuations one has to use Schneider's version for odd valuations - Theorem 1.5.2(b)). We call it Schneider's imbedding. However there is no direct analogue of "the cosine transform" description of the image of it. More delicate analysis is required; it is based (besides the irreducibility theorem) on a more detailed study of the action of $GL(n, \mathbb{R})$

on valuations and on functions (or, rather, sections of an equivariant line bundle) on partial flags. This requires more tools from infinite dimensional representation theory of the group $GL(n, \mathbb{R})$. We refer for the details to [14].

Another important property of the Fourier transform is that it intertwines the pull-back and push-forward on valuations. We will formulate this property in a non-rigorous way due to various technicalities making the formal statement heavier (see [15]). Let $f: V \rightarrow W$ be a linear map. Let $f^\vee: W^* \rightarrow V^*$ be the dual map between the dual spaces. Then the claim is that one should have

$$\mathbb{F}_V \circ f^* = (f^\vee)_* \circ \mathbb{F}_W, \quad (1.3)$$

where f^* is the pull-back under f , $(f^\vee)_*$ is the push-forward under $f^\vee$, and $\mathbb{F}_V$ and $\mathbb{F}_W$ are the Fourier transforms on V and W respectively. Notice that the equality (1.3) formally is ill-defined if f is not an isomorphism. This is due to the fact that $\mathbb{F}$ is formally defined only on the class of smooth valuations, while f^* and $(f^\vee)_*$ do not preserve this class. Nevertheless morally this equality should be true, but technically one should be more accurate.

Moreover one expects that in some sense the Fourier transform should commute with the exterior product:

$$\mathbb{F}(\phi \boxtimes \psi) = \mathbb{F}\phi \boxtimes \mathbb{F}\psi.$$

The difficulty here is that the exterior product of smooth valuations is usually not smooth.

As the last remark let us mention that it would be desirable to have a more direct construction of the Fourier transform. For example we still do not know how to describe it in terms of the construction of valuations using integration with respect to the normal cycle discussed below in Section 1.12.2.

1.12 General constructions of translation invariant convex valuations.

So far the only construction of valuations we have seen is the mixed volume. In this section we review some other general constructions of translation invariant continuous convex valuations. In Section 1.12.1 we describe briefly an array of examples coming from integral geometry; more complete treatment will be given in Fu's lectures. In Section 1.12.2 we describe another very general and useful construction via integration over the normal cycle of a set; this construction will be generalized appropriately to the context of valuations on manifolds in Section 2. There is yet another construction of valuations based on complex and quaternionic pluripotential theory. It is somewhat more specialized and will not be discussed here; we refer to [7], [13], and the survey [8].

1.12.1 Integral geometry.

Let us give a few basic examples which arise naturally in (Crofton style) integral geometry. The classical reference to this type of integral geometry is Santaló's book [56]. For further

discussion of this type of integral geometry and its relations to the valuations theory we refer to Fu's lectures, the book [45], and the articles [3], [19], [20], [21], [25], [33] (these recent results are surveyed by Bernig [22]).

Let $V = \mathbb{R}^n$ be the standard Euclidean space. Let $Gr_{k,n}$ denote the Grassmannian of all linear k -dimensional subspaces of it, and let $\bar{Gr}_{k,n}$ denote the Grassmannian of affine k -dimensional subspaces. It is not hard to check that the following expressions are continuous valuations invariant with respect to all isometries of $\mathbb{R}^n$:

$$\phi(K) = \int_{E \in Gr_{k,n}} V_i(pr_E(K)) dE, \quad (1.4)$$

$$\psi(K) = \int_{E \in \bar{Gr}_{k,n}} V_i(K \cap E) dE, \quad (1.5)$$

where dE denotes in both formulas a Haar measure on the corresponding Grassmannian, and $pr_E: \mathbb{R}^n \rightarrow E$ denotes the orthogonal projection. These expressions have been studied quite extensively in the classical integral geometry; they can be computed as integrals of certain expressions of the principal curvatures of the boundary ∂K , at least under appropriate assumptions on smoothness of it, see e.g. [56], [45]. Notice that Hadwiger's theorem implies that these valuations can be written as linear combinations of intrinsic volumes $V_0, V_1, \dots, V_n$; the coefficients can be computed explicitly.

Let us present analogous expressions from the Hermitian integral geometry of $\mathbb{C}^n$. Despite the obvious similarity to the Euclidean case, these expressions have been studied in depth only quite recently [3], [25], [33]. Let ${}^{\mathbb{C}}Gr_{k,n}$ denote the Grassmannian of complex linear k -dimensional subspaces of $\mathbb{C}^n$, and ${}^{\mathbb{C}}\bar{Gr}_{k,n}$ the Grassmannian of complex affine k -dimensional subspaces. Let us define in analogy to (1.4)-(1.5)

$$\phi(K) = \int_{E \in {}^{\mathbb{C}}Gr_{k,n}} V_i(pr_E(K)) dE, \quad (1.6)$$

$$\psi(K) = \int_{E \in {}^{\mathbb{C}}\bar{Gr}_{k,n}} V_i(K \cap E) dE, \quad (1.7)$$

where dE again denotes a Haar measure on the appropriate complex Grassmannian. It was shown in [3] that from valuations of the form (1.6) (or alternatively, (1.7)) one can choose a basis of unitarily invariant valuations in $Val(\mathbb{C}^n)$. Moreover in the same paper it was shown that the Fourier transform of a valuation of the form (1.6) has the form (1.7) with appropriately chosen i, k , and vice versa. Some different bases in unitarily invariant valuations have been constructed by Bernig-Fu [25] where they also computed several integral geometric formulas in $\mathbb{C}^n$, in particular the principal kinematic formula.

1.12.2 Normal cycle.

In this section we remind the notion of the normal cycle of a convex set and present a construction of translation invariant smooth valuations on convex sets in terms of it. In fact we will see that all such valuations can be obtained using this construction. One of the

important aspects of this construction is that it generalizes to a broader context of valuations on manifolds to be discussed in Section 2.

In this section we will fix again a Euclidean metric and an orientation on a vector space V , $\dim V = n$, for convenience of a geometrically oriented reader. However this metric is not necessary, and in Section 2.1 we describe an extension of the construction of normal cycle to any smooth manifold without any additional structure (not for convex sets of course, but for compact submanifolds with corners).

Let $K \in \mathcal{K}(V)$ be a convex compact subset of V . For any point $x \in K$ let us define the normal cone of K at x as a subset of the unit sphere S^{n-1} (see e.g [58], p. 70):

$$N(K, x) := \{u \in S^{n-1} \mid (u, y - x) \leq 0 \text{ for any } y \in K\}.$$

It is clear that $N(K, x)$ is non-empty if and only if x belongs to the boundary of K . Now define the normal cycle of K by

$$N(K) := \cup_{x \in K} \{(x, u) \mid u \in N(K, x)\}.$$

It is not hard to see that $N(K)$ is a closed subset of $V \times S^{n-1}$. Moreover it is locally bi-Lipschitz equivalent to $\mathbb{R}^{n-1}$,¹ and hence integrating of smooth differential $(n-1)$ -forms on $V \times S^{n-1}$ over $N(K)$ defines a continuous linear functional on such forms (more precisely $N(K)$ can be considered as an integral $(n-1)$ -current). A proof of the following result can be found in [18]; it is based on some geometric measure theory and previous work of Fu [28]-[30], [32] and other people [62], [63] on normal cycles (the references can be found in [18]).

Proposition 1.12.1. *Let ω be an infinitely smooth $(n-1)$ -form on $V \times S^{n-1}$. Then the functional*

$$K \mapsto \int_{N(K)} \omega$$

is a continuous valuation on $\mathcal{K}(V)$. If moreover ω is invariant with respect to translations in V then the above expression is a smooth translation invariant valuation in the sense of Definition 1.6.1.

Let us denote by $\Omega_{tr}^{n-1}(V \times S^{n-1})$ the space of infinitely smooth $(n-1)$ -forms on $V \times S^{n-1}$ which are invariant with respect to translations on V .

Proposition 1.12.2 ([9], Theorem 5.2.1). *The linear map $\mathbb{C} \oplus \Omega_{tr}^{n-1}(V \times S^{n-1}) \rightarrow Val^{sm}(V)$ given by*

$$(a, \omega) \mapsto a \cdot vol(K) + \int_{N(K)} \omega$$

is continuous and onto.

¹This fact was communicated to me by Joe Fu. Unfortunately I have no reference to it.

The proof of this theorem is based on the observation that the map in the proposition can be rewritten in metric free terms, such that it will commute with the action of the full linear group $GL(V)$. The irreducibility theorem implies that the image of this map is dense in $Val^{sm}(V)$. The fact that the image is closed follows from a rather general representation theoretical result due to Casselman and Wallach which says that any morphism between two $GL(V)$ -representations in Fréchet spaces satisfying appropriate technical conditions, has a closed image (see [9], Theorem 1.1.5, for a precise statement and references).

The kernel of this map was described by Bernig and Bröcker [23] by a system of differential and integral equations. Bernig has applied very successfully this description in classification problems of translation invariant valuations invariant under various groups transitive in spheres [19], [20], [21].

1.13 Valuations invariant under a group.

Let G be a compact subgroup of the group of orthogonal transformations of a Euclidean n -dimensional space V . We denote by Val^G the subspace of $Val(V)$ of G -invariant valuations. When $G = SO(n)$ the space Val^G was described by Hadwiger (see Section 1.3). There are examples of other groups, e.g. the unitary group $U(n/2)$, of particular interest to integral geometry. In fact whenever the space Val^G turns out to be finite dimensional we may hope to classify it explicitly in geometric terms and then apply this classification to integral geometry, for example to obtain generalizations of Crofton and principal kinematic formulas. The first general result in this direction is as follows.

Proposition 1.13.1 ([1]). *Let G be a compact subgroup of the orthogonal group. The space Val^G is finite dimensional if and only if G acts transitively on the unit sphere.*

Recall also that by Proposition 1.6.2 if G acts transitively on the sphere then $Val^G \subset Val^{sm}$. This equips Val^G with the product. Evidently we have also McMullen's decomposition

$$Val^G = \bigoplus_{i=0}^n Val_i^G.$$

Thus Val^G becomes a finite dimensional commutative associative graded algebra with unit. It satisfies the Poincaré duality and two versions of the hard Lefschetz theorem as in Section 1.10. Moreover it was shown by Bernig [20] that for such G all G -invariant valuations are even. Next $Val_1^G = \mathbb{C} \cdot V_1$, $Val_{n-1}^G = \mathbb{C} \cdot V_{n-1}$ by [4].

In topology there is an explicit classification of compact connected Lie groups acting transitively and effectively on spheres due to A. Borel and Montgomery-Samelson. There are 6 infinite lists

$$SO(n), U(n), SU(n), Sp(n), Sp(n) \cdot Sp(1), Sp(n) \cdot U(1),$$

and 3 exceptional groups

$$Spin(7), Spin(9), G_2.$$

Valuations in the case of $SO(n)$ were completely studied by Hadwiger [39]. The next interesting case is the unitary group $U(n)$. This case turned out to be more complicated than $SO(n)$ and in recent years there was a considerable progress in it. There is a complete

geometric classification [3], the description of the algebra structure [33], and the principal kinematic formula [25]. This is discussed in detail in Fu's lectures. For most of the other groups new strong results with applications to integral geometry were obtained recently by Bernig in a series of articles. We refer to his survey [22] reporting on the progress.

2 Valuations on manifolds.

The notion of valuation on smooth manifolds was introduced by the author in [10]. The goal of this section is to describe this notion, its properties, and some applications to integral geometry established in [9]-[11], [18], [15], [16]. In particular we extend the product construction to the setting of valuations on manifolds and explain its intuitive meaning. This intuitive interpretation is based on another useful notion of generalized valuation which establishes an explicit link between the valuations theory and a better studied notion of constructible functions. The usefulness of this comparison will be illustrated on several other examples. Next we introduce operations of pull-back and push-forward under smooth maps of manifolds in a number of important special cases generalizing familiar operations on smooth functions, measures, and constructible functions. All these structures are eventually used to define a general Radon type transform on valuations which generalizes the classical Radon transforms on smooth and constructible functions.

2.1 Definition of smooth valuations on manifolds; basic examples.

The original approach [10] to define smooth valuations on smooth manifolds was rather technical. In these notes we will follow a different, more direct and actually equivalent approach, which however might look not very natural and less motivated.

Let X be a smooth manifold of dimension n .² We describe a certain class of finitely additive measures on nice subsets of X (to be more precise, on compact submanifolds with corners). In our current approach this class is defined by the explicit construction of integration of a differential form with respect to the normal cycle. While in the original approach [9] this description was a theorem rather than a definition, it seems to be faster not to repeat all the intermediate steps leading to it. A reader may take Proposition 1.12.2 above as a possible justification for the current approach.

A submanifold with corners of X is a closed subset $P \subset X$ which is locally diffeomorphic to $\mathbb{R}_{\geq 0}^i \times \mathbb{R}^j$ where i, j are integers (then necessarily $0 \leq i + j \leq n$). We denote by $\mathcal{P}(X)$ the family of all compact submanifolds with corners. Basic examples from $\mathcal{P}(X)$ are compact smooth submanifolds, possibly with boundary. When $X = \mathbb{R}^n$ simplices, or more generally simple polytopes, of any dimension belong to $\mathcal{P}(X)$; however non-simplicial polytopes (such as the octahedron in $\mathbb{R}^3$) do not.

We are going to define the normal cycle of $P \in \mathcal{P}(X)$. Let T^*X denote the cotangent bundle of X . Let $\mathbb{P}_X$ denote the oriented projectivization of T^*X , namely $\mathbb{P}_X := (T^*X \setminus \underline{0})/\mathbb{R}_{>0}$

²All manifolds are assumed to be countable at infinity, i.e. presentable as a union of countably many compact subsets.

where $\underline{0}$ is the zero-section of T^*X , and $\mathbb{R}_{>0}$ is the multiplicative group of positive real numbers acting on T^*X by multiplication on the cotangent vectors. We call $\mathbb{P}_X$ the *cosphere bundle* since if one fixes a Riemannian metric on X then it induces identification of $\mathbb{P}_X$ with the unit (co)tangent bundle.

Let $P \in \mathcal{P}(X)$. Let $x \in P$ be a point. The *tangent cone* to P at x is the subset of the tangent space $T_x X$ of all ξ such that there exists a C^1 -smooth curve $\gamma: [0, 1] \rightarrow P$ such that $\gamma(0) = x$, $\gamma'(0) = \xi$. It is not hard to see that $T_x P \subset T_x X$ is a closed convex polyhedral cone. Let $(T_x P)^o$ denote the dual cone, namely

$$(T_x P)^o := \{\eta \in T_x^* X \mid \langle \eta, \xi \rangle \leq 0 \text{ for any } \xi \in T_x P\}.$$

This is a closed convex cone in T^*X . Now define the *normal cycle* of P by

$$N(P) := \cup_{x \in P} ((T_x P)^o \setminus \{0\}) / \mathbb{R}_{>0}.$$

It is well known (and easy to see) that $N(P)$ is a compact $n - 1$ -dimensional submanifold of $\mathbb{P}_X$ with singularities. Also it is Legendrian with respect to the canonical contact structure on $\mathbb{P}_X$ (though this fact will not be used explicitly in these lectures).

Remark 2.1.1. If $X = \mathbb{R}^n$ and $P \in \mathcal{P}(\mathbb{R}^n)$ is convex then this definition of the normal cycle coincides with the definition of the normal cycle from Section 1.12.2. Actually the normal cycle can be defined for other classes of sets: sets of positive reach (which includes convex compact sets in the case $X = \mathbb{R}^n$), and subanalytic sets when X is a real analytic manifold (see Fu [32] which is based on [28], [29], [30], [31], and develops further [27], [62], [63]). An essentially equivalent notion of characteristic cycle was developed in [42] for subanalytic sets using a different approach.

Below in this article we will assume for simplicity of exposition that X is oriented; this assumption can be easily removed. The orientation of X induces an orientation of the normal cycle of every subset.

Definition 2.1.2. A map $\phi: \mathcal{P}(X) \rightarrow \mathbb{C}$ is called a smooth valuation if there exist a measure μ on X and an $n - 1$ -form ω on $\mathbb{P}_X$, both infinitely smooth, such that

$$\phi(P) = \mu(P) + \int_{N(P)} \omega$$

for any subset $P \in \mathcal{P}(X)$.

Remark 2.1.3. This definition should be compared with Proposition 1.12.2. It can be shown that any translation invariant *convex* valuation on $\mathbb{R}^n$ which is smooth in the sense of Definition 1.6.1 can be naturally extended to a broader class of sets: to compact sets of positive reach and also to relatively compact subanalytic subsets of $\mathbb{R}^n$. This is done as follows: given a convex valuation $\phi \in \text{Val}^{sm}(\mathbb{R}^n)$, let us represent it (non-uniquely) in the form

$$\phi(K) = a \cdot \text{vol}(K) + \int_{N(K)} \omega,$$

where ω is a smooth translation invariant form. Then ϕ can be extended by the same formula to any subsets from the above broader class; this extension is independent of the choice of the form ω and the constant a .

It can be shown that every smooth valuation is a finitely additive functional in some precise sense [10].

Let us denote by $V^\infty(X)$ the space of all smooth valuations. The space $V^\infty(X)$ is the main object of study in what follows.

Example 2.1.4. (1) Any smooth measure on X is a smooth valuation. Indeed let us take $\omega = 0$ in Definition 2.1.2.

(2) The Euler characteristic χ is also a smooth valuation. This fact is less obvious. In the current approach, it is a reformulation of a version of the Gauss-Bonnet formula due to Chern [26] who has constructed μ and ω to represent the Euler characteristic; his construction depends on the choice of a Riemannian metric on X .

(3) The next example is very typical for integral geometry. Let $X = \mathbb{CP}^n$ be the complex projective space. Let ${}^{\mathbb{C}}Gr$ denote the Grassmannian of all complex projective subspaces of $\mathbb{CP}^n$ of a fixed complex dimension k . It is well known that ${}^{\mathbb{C}}Gr$ has a unique probability measure dE invariant under the group $U(n+1)$. Consider the functional

$$\phi(P) = \int_{E \in {}^{\mathbb{C}}Gr} \chi(P \cap E) dE.$$

Then $\phi \in V^\infty(\mathbb{CP}^n)$ (this follows e.g. from Fu [31]).

The space $V^\infty(X)$ is naturally a Fréchet space. Indeed it is a quotient space of the direct sum of Fréchet spaces $\mathcal{M}^\infty(X) \oplus \Omega^{n-1}(\mathbb{P}_X)$ by a closed subspace, where $\mathcal{M}^\infty(X)$ denotes the space of infinitely smooth measures. The subspace of pairs (μ, ω) representing the zero valuation was described by Bernig-Bröcker [23] in terms of a system of differential and integral equations.

One can show [10] that smooth valuations form a sheaf. That means that:

(1) we have the natural restriction map $V^\infty(U) \rightarrow V^\infty(V)$ for any open subsets $V \subset U \subset X$;

(2) given an open covering $\{U_\alpha\}$ of an open subset U , and $\phi \in V^\infty(U)$ such that the restriction $\phi|_{U_\alpha}$ of ϕ to all U_α vanishes, then $\phi = 0$;

(3) given an open covering $\{U_\alpha\}$ of an open U and $\phi_\alpha \in V^\infty(U_\alpha)$ for any α such that $\phi_\alpha|_{U_\alpha \cap U_\beta} = \phi_\beta|_{U_\alpha \cap U_\beta}$ for all α, β , then there exists (unique by (2)) $\phi \in V^\infty(U)$ such that $\phi|_{U_\alpha} = \phi_\alpha$.

2.2 Canonical filtration on smooth valuations.

The space of smooth valuations carries a canonical filtration by closed subspaces. In this section we summarize its main properties without giving a precise definition for which we refer to [10]. The important property of this filtration is that it partly allows to reduce the study of valuations on manifolds to the more familiar case of translation invariant convex valuations.

Let us denote by $Val(TX)$ the (infinite dimensional) vector bundle over X such that its fiber over a point $x \in X$ is equal to the space $Val^\infty(T_x X)$ of smooth translation invariant convex valuations on $T_x X$. By McMullen's theorem it has a grading by the degree of homogeneity: $Val^\infty(TX) = \bigoplus_{i=0}^n Val_i^\infty(TX)$.

Theorem 2.2.1. *There exists a canonical filtration of $V^\infty(X)$ by closed subspaces*

$$V^\infty(X) = W_0 \supset W_1 \supset \cdots \supset W_n, \quad n = \dim X,$$

such that the associated graded space $\bigoplus_{i=0}^n W_i/W_{i+1}$ is canonically isomorphic to the space of smooth sections $C^\infty(X, \text{Val}_i^\infty(TX))$.

Remark 2.2.2. (1) For $i = n$ the above isomorphism means that W_n coincides with the space of smooth measures on X .

(2) For $i = 0$ the above isomorphism means that W_0/W_1 is canonically isomorphic to the space of smooth functions $C^\infty(X)$. The epimorphism $V^\infty(X) \rightarrow C^\infty(X)$ with the kernel W_1 is just the evaluation-on-points map

$$\phi \mapsto [x \mapsto \phi(\{x\})].$$

Thus W_1 consists precisely of valuations vanishing on all points.

(3) Actually $U \mapsto W_i(U)$ defines a subsheaf $\mathcal{W}_i$ of the sheaf of valuations.

2.3 Integration functional.

Let $V_c^\infty(X)$ denote the subspace of $V^\infty(X)$ of compactly supported valuations. (The definition is obvious: a valuations ϕ is said to have a compact support if there exists a compact subset $A \subset X$ such that the restriction $\phi|_{X \setminus A} = 0$.) Clearly if X is compact then $V_c^\infty(X) = V^\infty(X)$. $V_c^\infty(X)$ carries a natural locally convex topology such that the natural imbedding to $V^\infty(X)$ is continuous (however in general this is not a Fréchet space, but rather a strict inductive limit of Fréchet spaces, see Section 5.1 of [11]).

The integration functional

$$\int_X : V_c^\infty(X) \rightarrow \mathbb{C}$$

is defined by $\int_X \phi := \phi(X)$.

Formally speaking, $\phi(X)$ is not defined when X is not compact. The formal way to define it is to choose first a large compact domain A containing the support of ϕ and set $\int_X \phi := \phi(A)$. Then one can show that this definition is independent of a large subset A . Moreover $\int_X$ is a continuous linear functional.

2.4 Product on smooth valuations on manifolds and Poincaré duality.

The product on smooth translation invariant convex valuations which was discussed in Section 1.7, can be extended to the case of smooth valuations on manifolds. We will describe below its main properties, and in Section 2.7 we will explain its intuitive meaning. However we present no construction of it in these notes. For the moment there are two different constructions of the product, both are rather technical. The first one was done in several steps. Initially the product was constructed by the author [9] on $\mathbb{R}^n$ (earlier the same construction was done even in a more specific situation [4] of convex valuations polynomial with respect to translations). Then this construction was extended by Fu and the author [18] to any smooth

manifold: it was shown that the product can be defined locally by a choice of a diffeomorphism of X with $\mathbb{R}^n$ and applying the above construction, and the main technical point was to show that the product is independent of the choice of this local diffeomorphisms. The second and rather different construction of the product was given recently by Bernig and the author [16]. This construction describes the product of valuations directly in terms of the forms μ, ω defining the valuations; it uses the Rumin operator and some other standard operations on differential forms. In comparison to the first construction, the second one has the advantage of being independent of extra structures on X (such as a coordinate system) and also some other technical advantages. However it is less intuitive than the first one. We summarize basic properties of the product as the following.

Theorem 2.4.1. *There exists a canonical product $V^\infty(X) \times V^\infty(X) \rightarrow V^\infty(X)$ which is*

- (1) *continuous;*
- (2) *commutative and associative;*
- (3) *the filtration $W_\bullet$ is compatible with it:*

$$W_i \cdot W_j \subset W_{i+j}$$

where we set $W_k = 0$ for $k > n = \dim X$;

- (4) *the Euler characteristic χ is the unit in the algebra $V^\infty(X)$;*
 - (5) *this product commutes with restrictions to open and closed submanifolds.*
- Thus V^∞ is a commutative associative filtered unital algebra over $\mathbb{C}$.*

Let us also add that the evaluation-on-points map $V^\infty(X) \rightarrow C^\infty(X)$ defined in Remark 2.2.2(2) is an epimorphism of algebras when $C^\infty(X)$ is equipped with the usual pointwise product.

An important property of the product is a version of the Poincaré duality. Consider the bilinear map

$$V^\infty(X) \times V_c^\infty(X) \rightarrow \mathbb{C}$$

defined by $(\phi, \psi) \mapsto \int_X \phi \cdot \psi$.

Theorem 2.4.2. *This bilinear form is a perfect pairing. In other words, the induced map*

$$V^\infty(X) \rightarrow (V_c^\infty(X))^*$$

is injective and has a dense image with respect to the weak topology.

2.5 Generalized valuations and constructible functions.

Definition 2.5.1. The space of generalized valuations is defined by

$$V^{-\infty}(X) := (V_c^\infty(X))^*$$

equipped with the weak topology. Elements of this space are called generalized valuations.

By Theorem 2.4.2 we have the canonical imbedding with dense image

$$V^\infty(X) \hookrightarrow V^{-\infty}(X).$$

Informally speaking, at least when X is compact, the space of valuations is essentially self-dual (up to completion). This imbedding also means that $V^{-\infty}(X)$ is a completion of $V^\infty(X)$ in the weak topology. Every smooth valuation can be considered as a generalized one.

The advantage of working with generalized valuations is that they contain constructible functions (described below) as a dense subspace. This gives a completely different point of view on valuations which is often useful especially on a heuristic level. Constructible functions have been studied quite extensively by the methods of algebraic topology (sheaf theory, see the book [42], Ch. 9). We will illustrate this below while discussing again the product on valuations, a Radon type transform, and the Euler-Verdier involution.

Let us define the space of constructible functions on X . In the literature there are various slightly different definitions of this notion, but the differences are technical rather than conceptual. For simplicity of the exposition we will assume in these notes, while talking about constructible functions, that X is a real analytic manifold.

Definition 2.5.2. A function $f: X \rightarrow \mathbb{C}$ on a real analytic manifold X is called constructible if it takes finitely many values, and for any $a \in \mathbb{C}$ the level set $f^{-1}(a)$ is subanalytic.

For the definition of a subanalytic set see Section 1.2 of [11], or for more details §8.2 of the book [42]. Constructible functions with compact support form a linear space which will be denoted by $\mathcal{F}(X)$. Moreover it is an algebra with pointwise product.

An important property of constructible functions is that they also admit a normal cycle such that if $P \in \mathcal{P}(X)$ is subanalytic then the normal cycle of the indicator function $\mathbb{1}_P$ is equal to the normal cycle of P (see [32], Ch. 9 of [42]). Using this notion we define the map

$$\Xi: \mathcal{F}(X) \rightarrow V^{-\infty}(X)$$

as follows. Let $\phi \in V_c^\infty(X)$ be given by $\phi(P) = \mu(P) + \int_{N(P)} \omega$ with smooth μ, ω . Then for any $f \in \mathcal{F}(X)$

$$\langle \Xi(f), \phi \rangle = \int_X f \cdot d\mu + \int_{N(f)} \omega.$$

The map Ξ is well defined, i.e. it is independent of a particular choice of μ, ω representing ϕ . Ξ is a linear injective map with dense image ([11], Section 8.1).

To summarize, we have a large space of generalized valuations with two completely different dense subspaces

$$V^\infty(X) \subset V^{-\infty}(X) \supset \mathcal{F}(X). \tag{2.1}$$

Notice that when X is compact, the image of the constant function $1 \in \mathcal{F}(X)$ in $V^{-\infty}(X)$ coincides with the image of the Euler characteristic $\chi \in V^\infty(X)$.

While working with valuations it is useful to keep in mind the imbeddings (2.1). The role of constructible functions in the theory of valuations is somewhat analogous to the role

of delta-functions in the classical theory of generalized functions (distributions). Often it is instructive to compare various structures on valuations with their analogues on constructible functions. We will see several examples of this below. Here we will show how it works for the integration functional and the filtration $W_\bullet$.

It was shown in [11] that the integration functional $\int_X: V_c^\infty \rightarrow \mathbb{C}$ extends uniquely by continuity in weak topology to the generalized valuations with compact support:

$$\int_X: V_c^{-\infty}(X) \rightarrow \mathbb{C}.$$

Let us restrict this functional to the subspace $\mathcal{F}_c(X)$ of constructible functions with compact support. It turns out that this restriction coincides with the integration with respect to the Euler characteristic; this operation is uniquely characterized by the property that for any compact subanalytic subset $P \subset X$

$$\int_X \mathbb{1}_P = \chi(P).$$

Let us consider now the filtration $W_\bullet$ on $V^\infty(X)$. Let W'_i denote the closure of W_i in $V^{-\infty}(X)$ with respect to the weak topology. By [11] the restriction of W'_i back to $V^\infty(X)$ coincides with W_i : $W'_i \cap V^\infty(X) = W_i$. Consider the induced filtration on constructible functions, namely

$$\mathcal{F}(X) = \mathcal{F}(X) \cap W'_0 \supset \mathcal{F}(X) \cap W'_1 \supset \cdots \supset \mathcal{F}(X) \cap W'_n.$$

It was shown in [11] that $\mathcal{F}(X) \cap W'_i$ consists of constructible functions with codimension of the support at most i . In particular $\mathcal{F}(X) \cap W'_n$ consists of functions with discrete support.

2.6 Euler-Verdier involution.

Let us give another example of an application of the comparison with constructible functions. The space of constructible functions has a canonical linear involution called the Verdier involution (see e.g. [42]). In the special case of functions on $\mathbb{R}^n$ which are constructible in a more narrow (polyhedral) sense this involution has been known for convexity experts under the name of Euler involution. We will see that it extends naturally to valuations, and this extension will be called the Euler-Verdier involution.

Here we will choose a sign normalization different from the standard one. Let us describe the Verdier involution σ (with a different sign convention) in a special case when a constructible function has the form $\mathbb{1}_P$ where P is a compact subanalytic submanifold with corners (the general case is not very far from this one using the linearity property of it). Then

$$\sigma(\mathbb{1}_P) = (-1)^{n-\dim P} \mathbb{1}_{\text{int } P},$$

where $\text{int } P$ denotes the relative interior of P . One has $\sigma^2 = Id$.

Theorem 2.6.1 ([11]). *(1) The involution σ extends (uniquely) by continuity to $V^{-\infty}(X)$ in the weak topology. This extension is also denoted by σ ;*

(2) σ preserves the class of smooth valuations and $\sigma: V^\infty(X) \rightarrow V^\infty(X)$ is a continuous linear operator (in the Fréchet topology);

(3) $\sigma^2 = \text{Id}$;

(4) $\sigma: V^\infty(X) \rightarrow V^\infty(X)$ is an algebra automorphism;

(5) σ preserves the filtration $W_\bullet$, namely $\sigma(W_i) = W_i$;

(6) for any smooth translation invariant valuation ϕ on $\mathbb{R}^n$ one has

$$(\sigma\phi)(K) = (-1)^{\deg \phi} \phi(-K)$$

where $\deg \phi$ denotes the degree of homogeneity of ϕ ;

(7) σ commutes with restrictions to open subsets (both for smooth and generalized valuations).

Remark 2.6.2. Though σ was defined above only on a real analytic manifold X , it can be defined on any smooth manifold as a continuous linear operator $\sigma: V^{-\infty}(X) \rightarrow V^{-\infty}(X)$. Then it satisfies the properties (2)-(7) of Theorem 2.6.1.

2.7 Partial product on generalized valuations.

In this section we discuss the promised intuitive meaning of the product on valuations. This interpretation was conjectured by the author [12] and proved rigorously by Bernig and the author [16]. It provides yet another example of the relevance of constructible functions to valuations.

Recall again that we have the imbedding of smooth valuations to generalized ones:

$$V^\infty(X) \subset V^{-\infty}(X).$$

One could try to extend the product on smooth valuations to $V^{-\infty}(X)$ say by continuity. Unfortunately this is not possible. The situation here is much analogous to what is known in the classical theory of generalized functions (see e.g. [41]). There the space of smooth functions $C^\infty(X)$ is naturally imbedded to the larger space of generalized functions $C^{-\infty}(X)$ which is a completion of it in the weak topology. The space $C^\infty(X)$ has its usual pointwise product. However this product does not extend to $C^{-\infty}(X)$ by continuity: for example no rigorous way is known how to take the square of the delta-function on $X = \mathbb{R}$. Nevertheless it is still possible to define a *partial* product on $C^{-\infty}(X)$. That roughly means that one can define a product of two generalized functions whose "singularities" are disjoint. The precise technical condition is formulated in the language of the wave front sets of generalized functions in the sense of Hörmander-Sato; we will not reproduce it here, but rather refer to [41]. This partial product is natural and satisfies some continuity properties ([37], Ch. VI §3).

In the case of valuations we have the following result.

Theorem 2.7.1 ([16]). *There exists a partial product on $V^{-\infty}(X)$ extending the product on $V^\infty(X)$. It is commutative and associative.*

We refer to [16] for the precise technical formulation when the partial product of two generalized valuations is defined. We notice only that the condition is also formulated in the language of wave front sets.

Now we can try to restrict the partial product on generalized valuations to constructible functions and see what we get. The answer is very natural: we just get their pointwise product (under certain technical assumptions on the functions guaranteeing that their product in $V^{-\infty}(X)$ is well defined). More precisely we have the following result.

Theorem 2.7.2 ([16]). *Let $P, Q \subset X$ be compact submanifolds with corners which intersect transversally. Then the product of $\mathbb{1}_P$ and $\mathbb{1}_Q$ in the sense of generalized valuations is well defined and is equal to $\mathbb{1}_{P \cap Q}$ (notice that under the transversality assumption, $P \cap Q$ is also a compact submanifold with corners).*

We did not give a formal definition of transversality of two submanifolds with corners. In the special case of submanifolds without corners, the definition is the usual one. In general the precise definition is given in [16]. Notice only that any two compact submanifolds with corners can be made transversal to each other by applying to one of them a generic diffeomorphism which is arbitrarily close (in the C^∞ -topology) to the identity map.

2.8 Few examples of computation of the product in integral geometry.

In this section we give few examples of computation of the product of valuations in the complex projective space $\mathbb{CP}^n$. These examples are very typical in integral geometry. We present a heuristic argument since hopefully it will clarify the intuition behind the product in applications.

First let us give few heuristic remarks of a general nature. Let P be a compact real analytic subset of a real analytic manifold X . As we have seen in Section 2.5, the indicator function $\mathbb{1}_P$ can be considered as a generalized valuation. Can we consider this non-smooth valuation as a finitely additive measure? The answer is: "essentially yes". This measure is defined only on nice compact subsets of X which are "transversal" to P . It is equal to

$$K \mapsto \chi(K \cap P).$$

We do not want to formalize this here, but this is the right way to think of $\mathbb{1}_P$ as a measure.

Let now $X = \mathbb{CP}^n$ with the Fubini-Study metric. Let us denote by ${}^{\mathbb{C}}G_l$ the Grassmannian of l -dimensional complex projective subspaces of $\mathbb{CP}^n$. Clearly it is equal to the Grassmannian of $l + 1$ -dimensional complex linear subspaces in $\mathbb{C}^{n+1}$. Let us consider the smooth $U(n + 1)$ -invariant valuations

$$\phi_l(K) := \int_{{}^{\mathbb{C}}G_l} \chi(K \cap E) dE \quad (2.2)$$

where dE is the Haar measure on ${}^{\mathbb{C}}G$ normalized somehow (we do not care about normalization constants). We claim that

$$\phi_l \cdot \phi_m = \begin{cases} c \cdot \phi_{l+m-n}, & l + m \geq n \\ 0, & l + m < n \end{cases} \quad (2.3)$$

where $c \neq 0$ is a normalizing constant depending on normalizations of Haar measures.

Let us give a heuristic proof of this equality. Using the discussion in the beginning of this section, we observe that

$$\phi_l(K) = \left(\int_{\mathbb{C}G_l} \mathbb{1}_E dE \right) (K)$$

where $\mathbb{1}_E$ is considered as a generalized valuation. Hence

$$\phi_l \cdot \phi_m = \int_{(E,F) \in \mathbb{C}G_l \times \mathbb{C}G_m} \mathbb{1}_E \cdot \mathbb{1}_F dE dF = \int_{\mathbb{C}G_l \times \mathbb{C}G_m} \mathbb{1}_{E \cap F} dE dF$$

where the last equality is due to Theorem 2.7.2. Since for generic projective subspaces E and F their intersection $E \cap F$ is a projective subspace of dimension $l + m - n$ for $l + m \geq n$ and empty otherwise, it follows that

$$\int_{\mathbb{C}G_l \times \mathbb{C}G_m} \mathbb{1}_{E \cap F} dE dF = c \int_{\mathbb{C}G_{l+m-n}} \mathbb{1}_M dM = c \cdot \phi_{l+m-n}.$$

Thus the equality (2.3) is proved.

Let us consider another important example of the product on $\mathbb{CP}^n$. We claim that the $U(n+1)$ -invariant valuation

$$K \mapsto \int_{\mathbb{C}G_l} V_i(K \cap E) dE \tag{2.4}$$

is equal to $\phi_l \cdot V_i$ where ϕ_l is defined by (2.2). First observe

$$V_i(K \cap E) = \mathbb{1}_{K \cap E}(V_i) = \int \mathbb{1}_{K \cap E} \cdot V_i$$

where $\mathbb{1}_{K \cap E}$ is considered as a generalized valuation, $\int$ in the last expression is the integration functional (i.e the evaluation on the whole space $\mathbb{CP}^n$); here both equalities are tautological by unraveling the definitions. Now we again use Theorem 2.7.2 to write (under transversality assumptions) $\mathbb{1}_{K \cap E} = \mathbb{1}_K \cdot \mathbb{1}_E$. Thus

$$\int \mathbb{1}_{K \cap E} \cdot V_i = \int \mathbb{1}_K \cdot \mathbb{1}_E \cdot V_i = (\mathbb{1}_E \cdot V_i)(K).$$

Thus the valuation (2.4) is equal to

$$\int_{\mathbb{C}G_l} \mathbb{1}_E \cdot V_i dE = \left(\int_{\mathbb{C}G_l} \mathbb{1}_E dE \right) \cdot V_i = \phi_l \cdot V_i$$

as it was claimed.

Finally let us compute a generalization of the two previous examples. We claim

$$\left(\int_{\mathbb{C}G_l} V_i(\bullet \cap E) dE \right) \cdot \left(\int_{\mathbb{C}G_m} V_j(\bullet \cap F) dF \right) = c' \cdot \int_{\mathbb{C}G_{l+m-n}} V_{i+j}(\bullet \cap M) dM \tag{2.5}$$

where c' is a constant which can be computed explicitly. By the previous two examples of this section, Example 1.7.4 from Section 1.7, and using the associativity and the commutativity of the product, we see that the left hand side of (2.5) is equal to

$$(\phi_l \cdot V_i) \cdot (\phi_m \cdot V_j) = (\phi_l \cdot \phi_m) \cdot (V_i \cdot V_j) = c' \cdot \phi_{l+m-n} \cdot V_{i+j} = \text{r.h.s. of (2.5)}.$$

Thus (2.5) is proved. Q.E.D.

2.9 Functorial properties of valuations.

We describe the operations of pull-back and push-forward on valuations under smooth maps of manifolds. These operations generalize the well known operation of pull-back on smooth and constructible functions, the operation of push-forward on measures, and integration with respect to the Euler characteristic along the fibers (also called push-forward) on constructible functions. However for the moment this is done rigorously only in several special cases of maps (say submersions and immersions). We believe however that these constructions can be extended to "generic" smooth maps as partially defined maps on valuations. The precise conditions under which the maps could be defined might be rather technical. For this reason we describe first the general picture heuristically. This picture should be considered as conjectural. Then we formulate several rigorous results with precise conditions under which one can define pull-back and push-forward on valuations. These special cases turn out to be sufficient to define rigorously the Radon type transform on valuations (again under some conditions) in the next section. The results of this section have been obtained by the author in [15].

Let us start with the heuristic picture. Let us denote by $V(X)$ a space of valuations on a manifold X without specifying exactly the class of smoothness (smooth, generalized, or something else). $V_c(X)$ denotes the subspace of $V(X)$ of compactly supported valuations. Let $f: X \rightarrow Y$ be a smooth map of manifolds. There should exist a partially defined linear map, called push-forward,

$$f_*: V_c(X) \dashrightarrow V_c(Y)$$

such that for any nice subset $P \subset Y$

$$(f_*\phi)(P) = \phi(f^{-1}(P)). \quad (2.6)$$

Since (smooth) measures are contained in $V(X)$, we can make their push-forward in the sense of valuations. Clearly this operation should coincide with the classical push-forward of measures.

It immediately follows from (2.6) that for the composition of maps we should have

$$(f \circ g)_* = f_* \circ g_*. \quad (2.7)$$

We expect that the following interesting property of push-forward f_* holds. It should extend somehow to a partially defined map on generalized valuations. Hence then f_* can be restricted to a partially defined map on constructible functions; it should be defined on constructible functions which are "in generic position" to the map $f: X \rightarrow Y$. We expect that

when f is a proper map (i.e. preimage of any compact set is compact) then on constructible functions f_* coincides with the integration with respect to the Euler characteristic along the fibers. Let us remind this operation assuming that X and Y are real analytic manifolds and f is a proper real analytic map. It is uniquely characterized by the following property: Let $P \subset X$ be a subanalytic compact subset. Then $(f_* \mathbb{1}_P)(y) = \chi(P \cap f^{-1}(y))$ for any point $y \in Y$. One can show that f_* maps constructible functions to constructible ones. We refer to Ch. 9 of [42] for further details.

The push-forward should be related to the filtration on valuations in the following way

$$f_*(W_i) \subset W_{i - \dim X + \dim Y}.$$

Also f_* should commute (up to a sign) with the Euler-Verdier involution.

Let us now discuss the pull-back operation

$$f^*: V(Y) \dashrightarrow V(X)$$

which should be a partially defined linear map in the opposite direction. Heuristically, f^* should be the dual map to f_* (recall from Section 2.4 that $V_c(X)$ and $V(X)$ are essentially dual to each other). The pull-back f^* should be a homomorphism of algebras of valuations (again, the product might be partially defined). We expect $f^* \chi = \chi$. Also f^* should preserve the filtration

$$f^*(W_i) \subset W_i,$$

and f^* should commute with the Euler-Verdier involution. Notice that since in particular $f^*(W_1) \subset W_1$, f^* induces a map between the quotients

$$f^*: V(Y)/W_1 \rightarrow V(X)/W_1.$$

But by Remark 2.2.2(2), $V(Y)/W_1$ coincides with functions on Y of an appropriate class of smoothness. In particular we should get a map

$$f^*: C^\infty(Y) \rightarrow C^{-\infty}(X).$$

We expect that this is the usual pull-back on smooth functions, i.e.

$$f^*(F) = F \circ f. \tag{2.8}$$

Now let us restrict f^* to constructible functions. We expect that it coincides again with the usual pull-back on constructible functions which is defined by the same formula (2.8).

Finally consider the restriction of f^* to (say smooth) measures on Y . In the classical measure theory the operation of pull-back of a measure does not exist. Nevertheless it is possible to define it as a valuation, at least under appropriate technical conditions on the map f . Let μ be a smooth measure on Y . Then, leaving all the technicalities aside, one should have

$$(f^* \mu)(P) = \int_{y \in Y} \chi(P \cap f^{-1}(y)) d\mu(y).$$

In particular if $f: X \rightarrow Y$ is a linear projection of vector spaces, and $P \subset X$ is a convex compact subset then $(f^*\mu)(P) = \mu(f(P))$ is the measure of the projection of P .

Now let us describe several rigorous results which will be used later. Let $f: X \rightarrow Y$ be a smooth map.

Case 1. Assume that f is a closed imbedding. Then the obvious restriction map $V^\infty(Y) \rightarrow V^\infty(X)$ defines the pull-back map f^* which is a linear continuous operator. Dualizing it, we get the push-forward map

$$f_*: V^{-\infty}(X) \rightarrow V^{-\infty}(Y)$$

which is a linear continuous (in the weak topology) operator. Notice that in this situation f_* does not preserve the class of smooth valuations.

It was shown in [15] that in this case $f_*(\mathbb{1}_P) = \mathbb{1}_{f(P)}$ for any compact submanifold with corners $P \subset X$. It was also shown that f^* can be extended to a partially defined map $V^{-\infty}(Y) \dashrightarrow V^{-\infty}(X)$ such that if $Q \subset Y$ is a compact submanifold with corners which is transversal to X then $f^*\mathbb{1}_Q$ is well defined in the sense of valuations and is equal to $\mathbb{1}_{X \cap Q}$, i.e. the pull-back on valuations is compatible with the pull-back on constructible functions.

Case 2. Assume that f is a proper submersion. Let us define the pull-back $f_*: V_c^\infty(X) \rightarrow V_c^\infty(Y)$ by $(f_*\phi)(P) = \phi(f^{-1}(P))$ for any compact submanifold with corners $P \subset Y$. Notice that in this case $f^{-1}(P)$ is a compact submanifold with corners, and $f_*\phi$ is indeed a smooth valuation. The map constructed is linear and continuous. Taking the dual map, we define the pull-back map

$$f^*: V^{-\infty}(Y) \rightarrow V^{-\infty}(X).$$

It was shown in [15] that in this case for any compact submanifold with corners $P \subset Y$ one has $f^*(\mathbb{1}_P) = \mathbb{1}_P \circ f = \mathbb{1}_{f^{-1}(P)}$. It was also shown that the push-forward f_* extends to a partially defined map on generalized valuations. However its compatibility with the integration with respect to the Euler characteristic along the fibers was proved only under rather ugly restrictions on the class of constructible functions.

2.10 Radon transform on valuations on manifolds.

In this section we combine the product, pull-back, and push-forward on valuations to define a Radon type transform on them. Before we introduce this notion, it is instructive to remind the general Radon transform on smooth functions following Gelfand, and less classical but still known Radon transform on constructible functions. These two completely different transforms can be considered as special cases of the general Radon transform on valuations. In our opinion, this is the most interesting property of the new Radon transform on valuations.

Definition 2.10.1. A double fibration is a triple of smooth manifolds X, Y, Z with two submersive maps

$$X \xleftarrow{p} Z \xrightarrow{q} Y$$

such that the map $Z \xrightarrow{p \times q} X \times Y$ is a closed imbedding.

To define a general Radon transform on smooth functions let us fix a double fibration as above and an infinitely smooth measure γ on Z . Let us also assume that $q: Z \rightarrow Y$ is proper. The Radon transform is the operator $R_\gamma: C_c^\infty(X) \rightarrow \mathcal{M}^\infty(Y)$ (where $\mathcal{M}^\infty(Y)$ denotes the space of smooth measures) defined by

$$R_\gamma f := q_*(\gamma \cdot p^* f), \quad (2.9)$$

where $p^* f = f \circ p$ is the usual pull-back on smooth functions, the product is just the usual product of a measure by a function, and q_* is the usual push-forward on measures. Notice that all classical Radon transforms on smooth functions have such a form. For example let us take $X = \mathbb{R}^n$, Y the Grassmannian of affine k -dimensional subspaces, and Z the incidence variety, i.e. $Z = \{(x, E) \in X \times Y \mid x \in E\}$. Let γ be a Haar measure on Z invariant under the group of all isometries of $\mathbb{R}^n$. Then R_γ is the classical Radon transform given by integration of a function on $\mathbb{R}^n$ over all affine k -dimensional subspaces. There is a very extensive literature on this subject, see e.g. [34], [35], [40].

Let us recall the Radon transform with respect to the Euler characteristic on constructible functions. It was studied for the real projective spaces and a somewhat restrictive class of constructible functions by Khovanskii and Pukhlikov [46]; their work has been motivated by the earlier work of Viro [61] on Radon transform on complex constructible functions on the complex projective spaces. We will discuss and generalize the Khovanskii-Pukhlikov result in the next section. For subanalytic constructible functions and other spaces the Radon transform with respect to the Euler characteristic was studied by Schapira [57]. Thus let

$$X \xleftarrow{p} Z \xrightarrow{q} Y$$

be a double fibration of real analytic spaces with real analytic maps p, q . We assume again that q is proper. Let us denote by $\mathcal{F}(X)$ the space of constructible functions as defined in Section 2.5. One defines the Radon transform $R: \mathcal{F}(X) \rightarrow \mathcal{F}(Y)$ by

$$Rf := q_* p^*(f), \quad (2.10)$$

where p^* denotes the usual pull-back on (constructible) functions, and q_* is the integration with respect to the Euler characteristic along the fibers of q .

With these preliminaries let us introduce the Radon transform on valuations. We fix a double fibration as above with the map q being proper. Let us fix a smooth valuation $\gamma \in V^\infty(Z)$. Define the Radon transform on valuations $\mathcal{R}_\gamma: V^\infty(X) \rightarrow V^{-\infty}(Y)$ by

$$\mathcal{R}_\gamma(\phi) = q_*(\gamma \cdot p^* \phi),$$

where p^* and q_* are the pull-back and push-forward on valuations respectively, and the product with γ is taken in the sense of valuations. It was shown in [15] that the operator $\mathcal{R}_\gamma$ is a well defined continuous linear operator.

Let us comment on some of the technical difficulties in this construction. Usually $p^* \phi$ is not a smooth valuation, though ϕ is. Thus we have to multiply the smooth valuation

γ by the non-smooth $p^*\phi$. This is always possible in the class of generalized valuations, but the product is not a smooth valuation. Next we have to take the push-forward of this generalized valuation. The push-forward of a generalized valuation under a general proper submersion is not always defined, but only under some rather technical condition of "generic position" of "singularities" of the valuation with respect to the map q . Fortunately this technical condition is satisfied for valuations of the form $\gamma \cdot p^*\phi$ with smooth ϕ . It was also shown in [15] that under extra assumptions on the double fibration the image $\mathcal{R}_\gamma(V^\infty(X))$ is contained in smooth valuations. Also under a similar extra assumption $\mathcal{R}_\gamma$ can be extended uniquely by continuity in the weak topology to generalized valuations $V^{-\infty}(X)$. An example satisfying both assumptions will be considered in the next section.

Let us discuss now the relation of the new Radon transform on valuations to the classical Radon transforms discussed above in this section. First let us assume that the valuation $\gamma \in V^\infty(Z)$ is in fact a smooth measure considered as a smooth valuation. Then the Radon transform

$$\mathcal{R}_\gamma: V^\infty(X) \rightarrow V^{-\infty}(Y)$$

vanishes on $W_1 \subset V^\infty(X)$. Indeed $p^*(W_1) \subset W_1$, and $\gamma \cdot W_1 = 0$ since γ is a measure. Hence $\mathcal{R}_\gamma$ factorizes (uniquely) via the quotient $V^\infty(X)/W_1 = C^\infty(X)$. Notice also that in this case $\mathcal{R}_\gamma$ takes values in measures, in fact in infinitely smooth ones. Hence we get a map $C^\infty(X) \rightarrow \mathcal{M}^\infty(Y)$. It was shown in [15] that this map coincides with the classical Radon transform R_γ defined by (2.9).

Let us consider another extremal case of $\mathcal{R}_\gamma$ with $\gamma = \chi$ being the Euler characteristic. In this case our discussion will be less rigorous. First assume that $\mathcal{R}_\gamma$ extends naturally to a partially defined map on generalized valuations $V^{-\infty}(X) \dashrightarrow V^{-\infty}(Y)$. We expect that its restriction to the class of constructible functions coincides with the Radon transform with respect to the Euler characteristic defined previously by (2.10). This result was proved rigorously in [15] in very special circumstances. It is desirable to make the result rigorous under more general assumptions.

2.11 Khovanskii-Pukhlikov type inversion formula for the Radon transform on valuations on $\mathbb{RP}^n$.

Let us consider the Radon type transform on valuations in the following special case. Let $X = \mathbb{RP}^n$ be the real projective space, i.e. the manifold of lines in $\mathbb{R}^{n+1}$ passing through the origin. Let $Y = \mathbb{RP}^{n\vee}$ be the dual projective space, i.e. the manifold of linear hyperplanes in $\mathbb{R}^{n+1}$. Let $Z \subset X \times Y$ be the incidence variety

$$Z := \{(l, E) \in \mathbb{RP}^n \times \mathbb{RP}^{n\vee} \mid l \subset E\}.$$

We have the double fibration

$$\mathbb{RP}^n \xleftarrow{p} Z \xrightarrow{q} \mathbb{RP}^{n\vee}$$

where p, q are the obvious projections. All the manifolds and maps are real analytic.

We consider the Radon transform

$$\mathcal{R}_\chi: V^\infty(\mathbb{RP}^n) \rightarrow V^{-\infty}(\mathbb{RP}^{n\vee})$$

with the kernel $\gamma = \chi$ being the Euler characteristic on Z . In this case

$$\mathcal{R}_\chi = q_* p^*.$$

It was shown in [15] that the image of this transformation is contained in smooth valuations, and $\mathcal{R}_\chi: V^\infty(\mathbb{RP}^n) \rightarrow V^\infty(\mathbb{RP}^{n^\vee})$ is continuous. Moreover this operator extends (uniquely) to a continuous linear operator, also denoted by $\mathcal{R}_\chi$, on generalized valuations equipped, as usual, with the weak topology:

$$\mathcal{R}_\chi: V^{-\infty}(\mathbb{RP}^n) \rightarrow V^{-\infty}(\mathbb{RP}^{n^\vee}).$$

It was shown in [15] that $\mathcal{R}_\chi$ is invertible for odd n , and for even n its kernel consists precisely of multiples of the Euler characteristic. In both cases there is an explicit inversion formula (in the latter case, up to a multiple of the Euler characteristic); it generalizes and was motivated by the Khovanskii-Pukhlikov inversion formula for constructible functions [46]. In order to state the result let us consider the analogous operator in the opposite direction

$$\mathcal{R}_\chi^t: V^{-\infty}(\mathbb{RP}^{n^\vee}) \rightarrow V^{-\infty}(\mathbb{RP}^n),$$

namely

$$\mathcal{R}_\chi^t := p_* q^*.$$

Theorem 2.11.1 ([15]). *For any generalized valuation $\phi \in V^{-\infty}(\mathbb{RP}^n)$ one has*

$$(-1)^{n-1} \mathcal{R}_\chi^t \mathcal{R}_\chi(\phi) = \phi + \frac{1}{2}((-1)^{n-1} - 1) \left(\int_{\mathbb{RP}^n} \phi \right) \cdot \chi. \quad (2.11)$$

Let us say a few words on the proof of this theorem. After all the operators involved were defined, the next technically non-trivial step was to show that the restriction of $\mathcal{R}_\chi$ to a rather special class of constructible functions, which is still dense in $V^{-\infty}(\mathbb{RP}^n)$, coincides with the Radon transform with respect to the Euler characteristic on constructible functions; also an analogous result holds for $\mathcal{R}_\chi^t$. Then Theorem 2.11.1 follows immediately by continuity from the Khovanskii-Pukhlikov inversion formula for constructible functions which claims precisely the identity (2.11) for such functions in place of ϕ .
